

Parametric estimates of total tree richness in Amazon

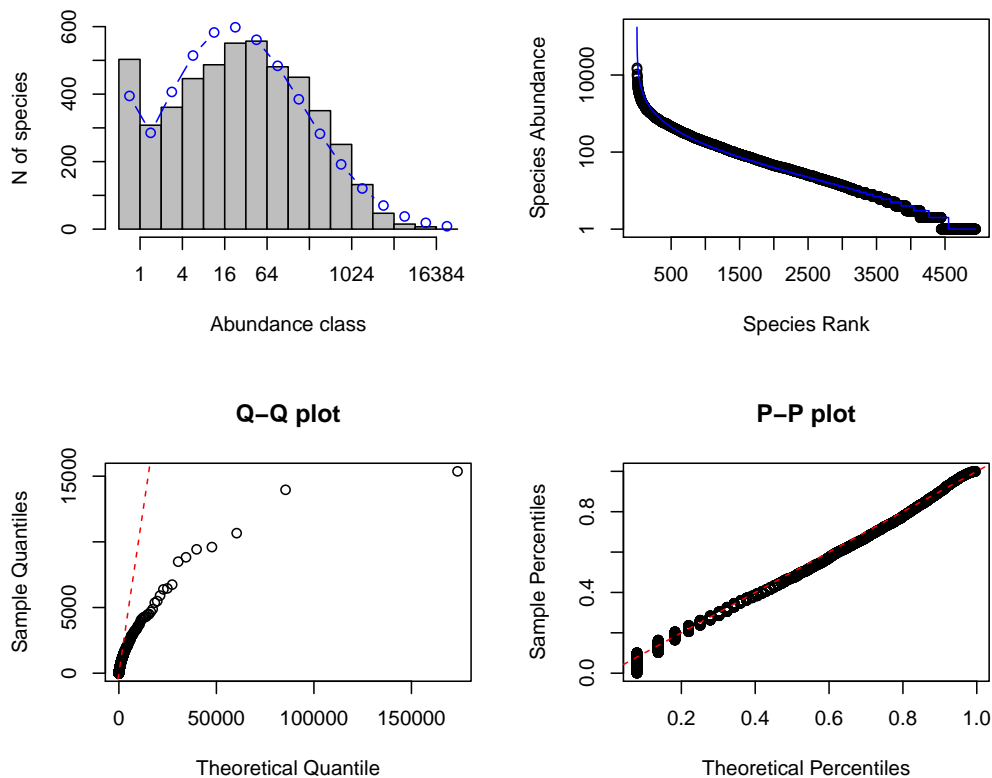

Han Ter Steege, Paulo Inácio Prado, Renato Lima, ATDN

July 19, 2018

Poisson lognormal

Seems to overestimate the abundance of the most abundant species (see qq-plots)

```
p1n <- fitpoilog(y)
par(mfrow=c(2,2))
plot(p1n)
par(mfrow=c(1,1))
```

Species richness estimation from the underlying lognormal

Still, let's use the estimated coefficients to estimate total species richness. The estimated parameters of the Poilog are:

```
(pln.cf <- coef(pln))

##      mu      sig
## 2.778902 2.477996
```

In this model the observed SADs is a Poisson sample of a lognormal SAD of the whole community. The parameter σ of the Poilog estimates the same parameter of the underlying lognormal. The parameter μ of the Poilog has

the following relationship with the corresponding parameter of the sampled lognormal (M):

$$M = \mu - \ln(p)$$

where p is the proportion of the community that has been sampled (Bulmer, 1974; Saether et al., 2013). As the total sampled area is 1.9×10^3 ha and the total area of Amazon is 5.5×10^8 ha, $p = 3.4545455 \times 10^{-6}$. Therefore, we have $M = 15.3547215$.

The mean of the lognormal distribution is

$$E[X] = e^{M + \frac{\sigma^2}{2}}$$

And then this model says that the regional SAD is lognormal with an average number of trees/species of

```
pln.cf <- unname(pln.cf)
Mu <- pln.cf[1] - log(1.9e3/5.5e8)
(mean.ln <- exp(Mu + pln.cf[2]^2/2))

## [1] 100428076
```

The estimated richness is then the total number of trees in the region divided by the mean above:

```
## Total number of trees (average density x area)
Tot.t <- 567*5.5e8
## Estimated number of species
(pln.S <- Tot.t/mean.ln)

## [1] 3105.207
```

Rather disappointing. I guess that the problem is the assumption that the pooled samples can be approximated by a Poisson sample of the entire tree community of Amazon (pretty unrealistic indeed).

Estimating species richness directly from PLN

An alternative way ¹ to estimate total number of species in the sampled metacommunity is simply to calculate the value of the Poisson-lognormal

¹I guess this is the way recommended by developers of the *poilog* package, to be checked

fitted to the data at the zero value. That is, to estimate the probability value assigned to species that had zero abundance in the sample. Simple as that:

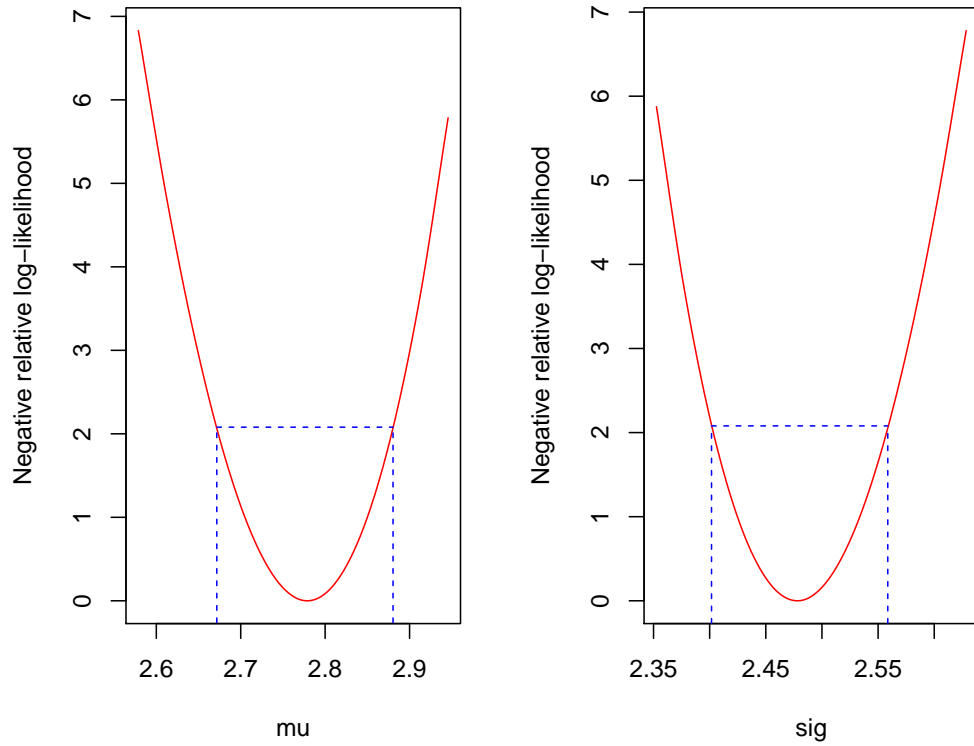

```
(pln.d0 <- dpoilog(0, mu = pln.cf[1], sig=pln.cf[2]))  
## [1] 0.1120095
```

That is, an estimate that the recorded species are 89% of the total number of species. This gives an estimate of 5571 species.

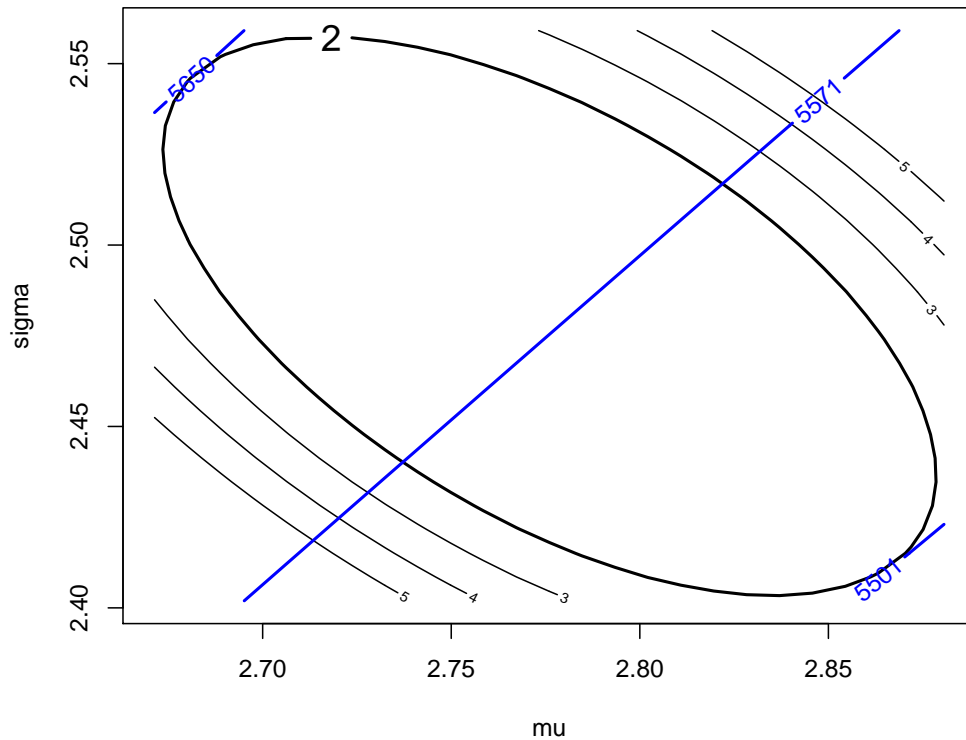

Likelihood and confidence intervals

Confidence profiles for both parameters are quite well-behaved (parabolic) and so match frequentist confidence intervals:

```
pln.prf <- profile(pln)  
par(mfrow=c(1,2))  
plotprofmle(pln.prf)  
par(mfrow=c(1,1))  
(pln.ci <- confint(pln.prf))  
  
##          2.5 %   97.5 %  
## mu  2.675600 2.876732  
## sig 2.404746 2.555894  
  
(pln.li <- likelregions(pln.prf))  
  
## Likelihood regions for ratio = 2.079442  
##  
## mu:  
##      lower    upper  
## [1,] 2.671338 2.880652  
##  
## sig:  
##      lower    upper  
## [1,] 2.401954 2.559099
```

The likelihood interval of total species richness can be estimated visually from the likelihood surface. Using the likelihood ratio of two (bold black isoline) we see that the likelihood interval for total species richness from PLN is ca 5500 – 5650:

Because confidence intervals of the estimated parameters are very close to likelihood intervals we have a similar result using one or another interval to estimate a interval for the total species richness. But the likelihood surface help us by showing that we have to use the upper bound of μ CI with the lower bound of σ CI to get the lower bound of species richness (and the opposite for the upper bound):

```
## Lower bound of S
Sobs / (1 - dpoilog(0, pln.ci[1,2], pln.ci[2,1]))

## [1] 5493.925

## Upper bound
Sobs / (1 - dpoilog(0, pln.ci[1,1], pln.ci[2,2]))

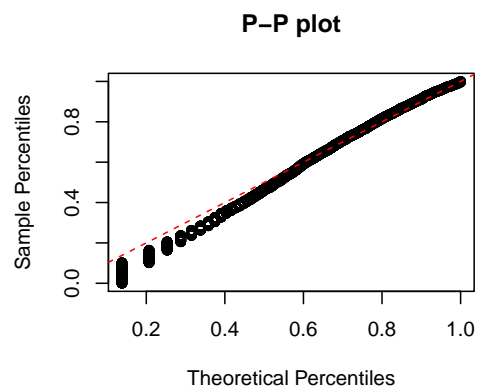

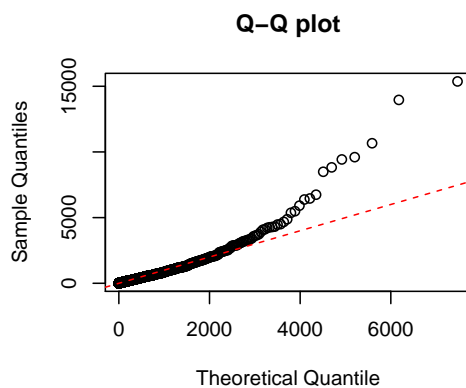

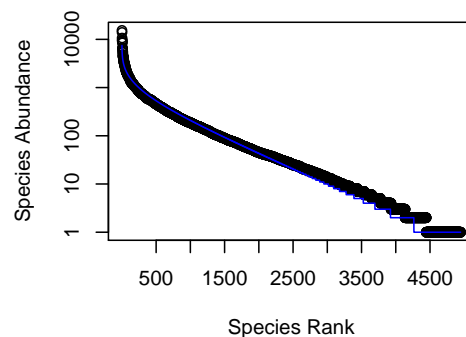

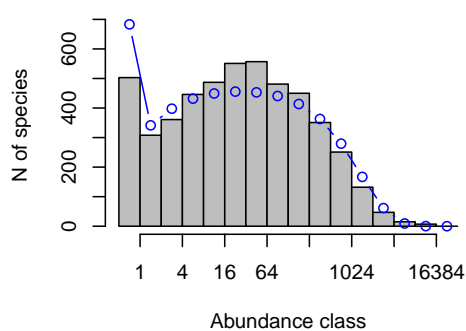

## [1] 5657.733
```

Still much lower than the estimates provided by log-series or negative binomial.

Log-series

Log-series seems to overestimate the number of singletons and to underestimate the abundance of species with intermediary abundances (between 16 and 64 individuals, see octave plot). Also, qq-plots show that the model underestimates the larger abundances.

```
y.ls <- fitls(y)
par(mfrow=c(2,2))
plot(y.ls)
par(mfrow=c(1,1))
```

Estimate of species richness

Well, you have that stuck in your brain, I suppose. But just for the records:

```
alpha <- coef(y.ls)[[2]]
(S.ls <- alpha*log(1 + Tot.t/alpha))

## [1] 13631.92
```

And here is the confidence interval for Fisher's α and the interval for estimated total richness from these values

```
(ls.ci <- confint(y.ls))

##      2.5 %    97.5 %
## 629.8799 740.3396

## Estimated species richness for lower bound of alpha's IC
ls.ci[1]*log(1 + Tot.t/ls.ci[1])

##      2.5 %
## 12610.36

ls.ci[2]*log(1 + Tot.t/ls.ci[2])

##      97.5 %
## 14702.17
```

Negative binomial

Here I use the method proposed by Tovo et al. (2017). The first step is to fit a negative binomial to the abundances in the sample. I did that with the *VGAM* package (as the authors did) and also with the *sads* package. The results were similar, and the fit looks identical to those provided by the log-series (but has much lower AIC value, see below).

```

## With VGAM
y.nb <- vglm(y ~ 1, posnegbinomial)
## With sads
y.nb2 <- fitnbinom(y, start.value=c(size=0.3, mu=mean(y)))
## Comparing:
exp(coef(y.nb))

## (Intercept):1 (Intercept):2
## 47.98400878 0.04074046

coef(y.nb2)

## size mu
## 0.04163341 48.91066826

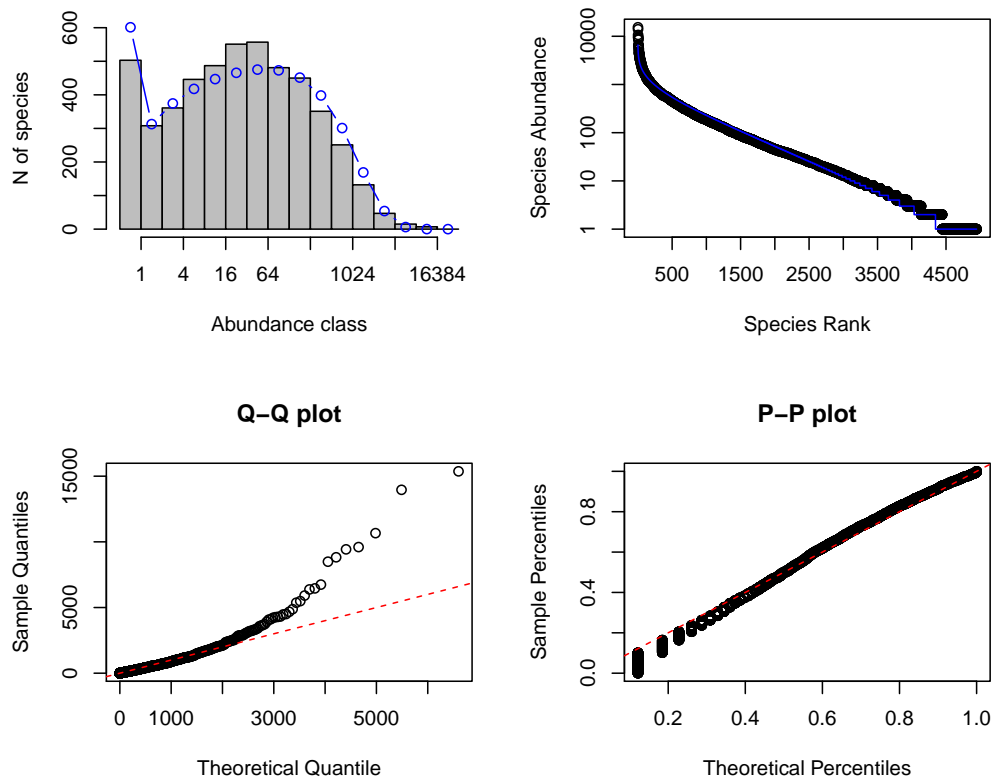

```

```

par(mfrow=c(2,2))
plot(y.nb2)
par(mfrow=c(1,1))

```

Estimate of species richness

Following the recipe of Tovo et al. (2017):

```
cf.nb <- coef(y.nb2)
csi.p <- unname(cf.nb[2]/(sum(cf.nb)))
csi <- csi.p/(p1+(1-p1)*csi.p)
## Estimated number of species
(S.est <- unname(Sobs*(1-(1-csi)^cf.nb[1]) / (1-(1-csi.p)^cf.nb[1])))

## [1] 10838.57
```

I did a simple function to automate the calculations and to return the confidence intervals, based on the confidence intervals of the coefficients of

the NB fit (see file `functions.R`)

```
tovo(fit = y.nb2, p = p1, CI=TRUE)

## Estimated species richness: 10838.57
## 95% CI: 10129.92 - 11753.85
```

Model selection

Among the three models, the Negative Binomial provides the best fit:

```
AICtab(pln, y.nb2, y.ls)

##      dAIC df
## y.nb2  0.0  2
## y.ls  26.3  1
## pln   32.4  2
```

Parametric estimates from occupancies

A quick exploration of models for the distribution of occupancies (that is, the proportion of plots in which each species has been recorded). Such distribution captures a bit of the spatial aggregation of species.

I tried two tentative approaches. The first one was to calculate the occupancies (that is the proportion of plots in which each species has been recorded) and then I fitted a beta distribution to these values. To take into account undetected species I tried to truncate this continuous distribution at different points.

The second approach was to fit the distribution of frequencies (the number of plots out of the total of 1900 in which each species has been recorded) to a beta-binomial distribution. Because this is a discrete distribution, truncation is at a single point (species with with zero frequency).

In both cases I assumed that the occupancies of the species follow a beta distribution, and that the observed frequencies were the result of independent 1900 trials for each species, in which the number of occupied plots follow

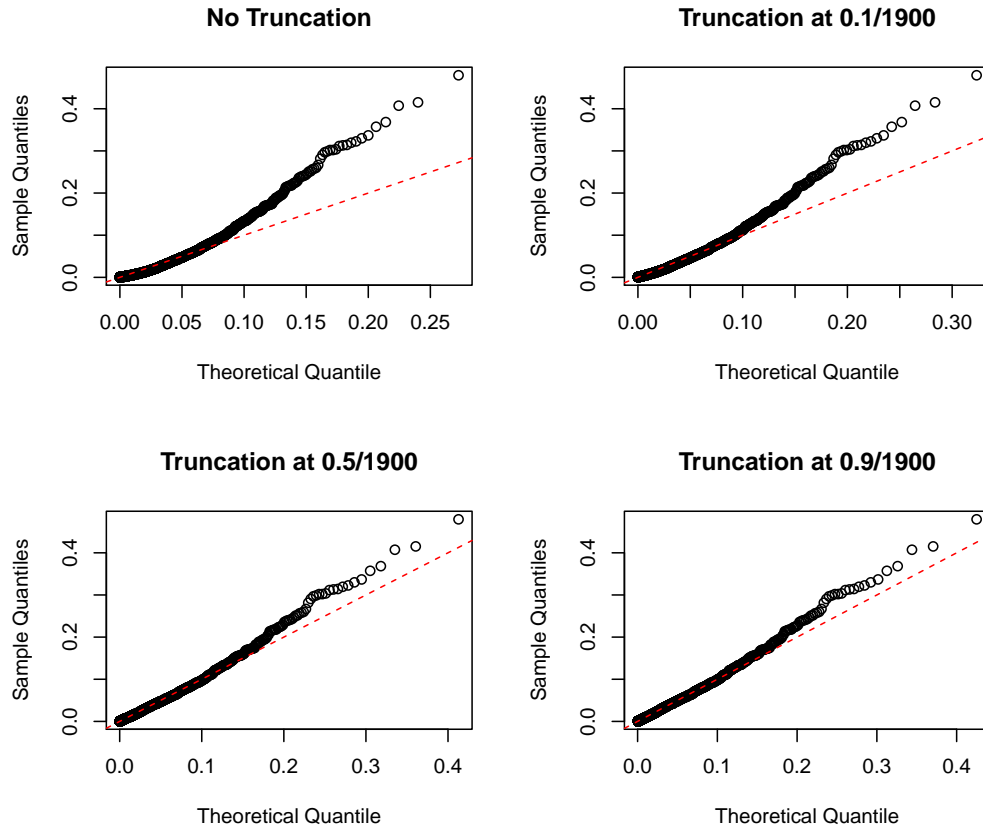

a binomial distribution. Hence the compound beta-binomial distribution that underlies both approaches. With this distribution we can estimate the proportion of undetected species and then the total number of species.

Truncated Beta distribution

The beta distribution is used to describe a distribution of bounded continuous variables like probabilities. We can think observed occupancies as estimates of the probabilities of occurrence of each species in a plot.

Because species with low occupancy values have lower detectability, the distribution should give more weight for the lower values of occupancies, as they are underrepresented in the sample. A first-order approximation is to truncate the beta distribution at $1/(\text{number of plots})$.

I then fitted the distribution of occupancies to beta distributions without truncation and truncated at 0.1/1900, 0.5/1900 and 0.9/1900. The code for fitting with maximum likelihood is in the source file of this document. Below I show the QQplots of predicted x observed values, which shows that truncation above 0.5/1900 clearly improves the fit:

And the model selection shows that the truncation at 0.9/1900 provides a much better fit:

```
AICtab(f.beta, f.betat.1, f.betat.5, f.betat.9)

##           dAIC    df
## f.betat.9      0.0  2
## f.betat.5 1091.5  2
## f.betat.1 2469.0  2
## f.beta    3186.2  2
```

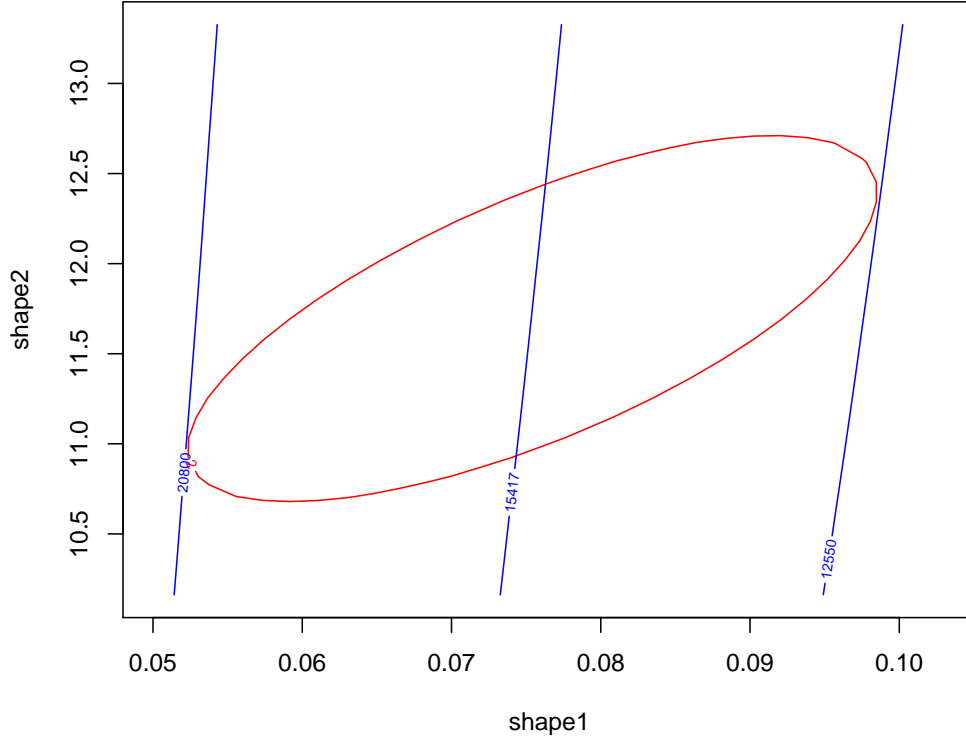

Estimate of species richness

```
## [1] 5637.334
## [1] 6431.079
## [1] 15417.45
## [1] 7481742
```

If we assume that species occur in the plots independently at with different values of occupancies (described by the beta distribution fitted above), the distribution of frequencies (number of occupied plots) follows a **beta-binomial distribution**. Because species that have not occurred in any plot are undetected, the beta-binomial distribution of observed frequencies is truncated at zero. The full distribution nevertheless returns the probability of zero frequency, which estimates the proportion of species not recorded. With this and the number of observed species we can estimate the total number of species. I did a function to do this (see scripts at `functions.R`) and got the following:

Truncation	Estimated richness
None	5637
0.1/1900	6431
0.5/1900	15417
0.9/900	7481742

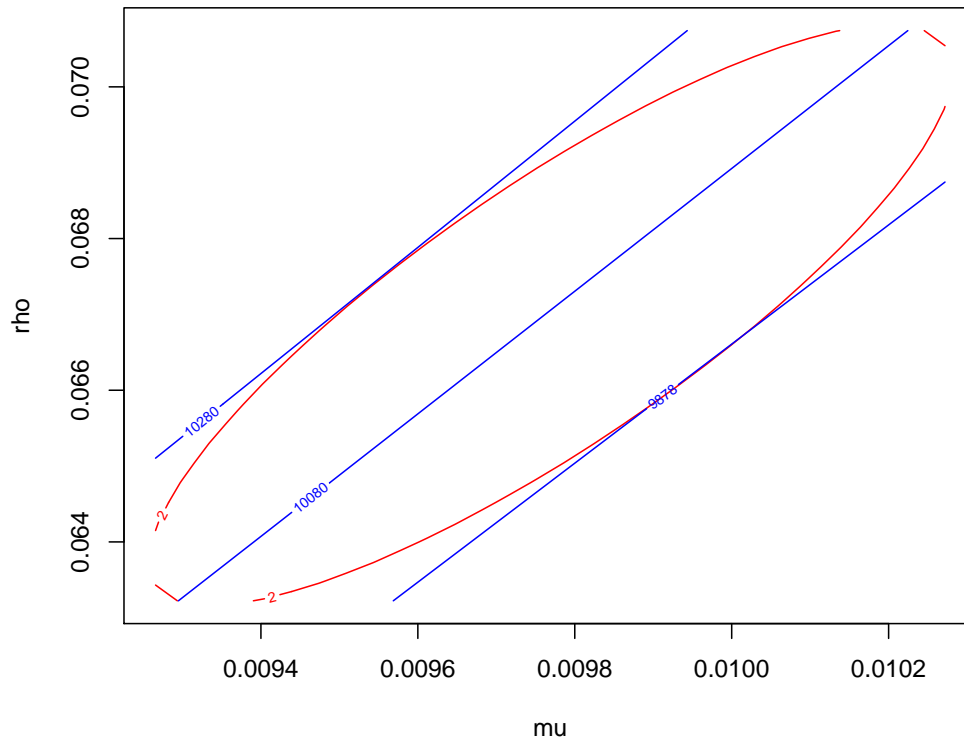

The distribution truncated at 0.9/1900 gives unrealistic estimates, so I'll follow with the model with truncation at 0.5/1900. With the likelihood surface I get a likelihood interval for the richness estimated by this model of 12550–20800.

Truncated beta-binomial

Another easy way to get species richness estimates from the beta-binomial is to fit this distribution directly to the observed frequencies. This distribution is zero-truncated to account for the unobserved species. In this case only the binomial distribution that composes the beta-binomial is truncated. To truncate also the beta compounding distribution we would need Bayesian models.

With this model I got an estimated total richness of 1.008×10^4 , with an likelihood interval of $9878 - 10280$.

Non-parametric estimates

Results of the non-parametric indices available in the package *SPECIES* (Wang, 2011). Only the 'Penalized non-parametric maximum likelihood estimate' from Wang, Lindsay (2005) is close the number of species recorded in Amazon. The others estimate 5000 species.

```
Ab <- as.data.frame(table(dados$N.ind))
names(Ab) <- c("j", "n_j")
Ab$j <- as.integer(Ab$j)
##jackknife method
(Sj <- jackknife(Ab,k=5))
```

```

Some thoughts

The estimates provided by non-parametric and also the parametric ones with strong assumptions of random and independent dispersion of species across space (which implies in describing the plots as Poisson samples) were consistently below the number of species currently recorded for the Amazon.

On the other hand, parametric estimates based on models that approximates some effect of a large beta-diversity provided consistently larger values, which encompassed the known number of species. Such beta-diversity effect is approximated in different ways. Log-series assumes an open metacommunity with an infinite number of species, negative binomial describes SADs with a variance higher than those expected by an independent distribution of species, and beta and beta-binomial models capture spatial aggregation of species. Still to be checked, the only non-parametric estimate that was

above 10,000 has also a similar effect by allowing a different detectability for each species (Wang, Lindsay, 2005). I think that the key message here is that beta-diversity matters a lot to get a better estimate. And also that those models that performed better are still rough approximations.

Also, I think that the comparison of the saturation curves of the estimators you did for the Amazon is nice. Many of them seem to stabilize well below the known number of species, while others do show an increasing trend. I think this may be valuable to discuss the quality of the estimates available for the Amazon. I would not venture in general evaluations of the estimators because there is already a ton of papers about that, so I think we do not need the simulated data.

Finally, I found interesting that some models provided a good fit to a distribution but did not provide a good estimate of species richness. The obvious explanation is that the approximation any model does may break down when you use it in extrapolations. But as obvious it may sound I think it is an important issue concerning the estimation of species richness.

So, I can see a paper that makes a comprehensive review of the estimates available for Amazon (plus Mata Atlântica, maybe?) and discuss the point above. A nice main figure would be a point-and-error-bars of all estimates.

Next steps

Not sure if for the same paper, but I would proceed with the idea of a model that improves assumptions about a large beta-diversity. My first guess is a minimum model that assumes different degrees of aggregation for each species. My first choice is a compound Negative binomial-Lognormal distribution. This is hard to fit by traditional methods, but it is doable with simulation and ABC (Approximate Bayesian Computation). To parameterize simulations we can use the empirical matrix of species x sites. I started to work in this idea with Renato and I have some preliminary R codes of a bootstrap estimator. The *SADISA* package uses a similar approach (using the information of replicate samples from the same metacommunity).
